ABSTRACT

Here we describe the first results of the ALHAMBRA survey which provides *cosmic tomography* of the evolution of the contents of the Universe over most of Cosmic history. Our novel approach employs 20 contiguous, equal-width, medium-band filters covering from 3500 Å to 9700 Å, plus the standard JHK_s near-infrared bands, to observe a total area of 4 square degrees on the sky. The

optical photometric system has been designed to maximize the number of objects with accurate classification by Spectral Energy Distribution type and redshift, and to be sensitive to relatively faint emission features in the spectrum. The observations are being carried out with the Calar Alto 3.5m telescope using the wide field cameras in the optical, LAICA, and in the NIR, Omega-2000. The first data confirm that we are reaching the expected magnitude limits (for a total of 100 ksec integration time per pointing) of $AB \leq 25$ mag (for an unresolved object, $S/N = 5$) in the optical filters from the blue to 8300 Å, and from $AB = 24.7$ to 23.4 for the redder ones. The limit in the NIR, for a total of 15 ks exposure time per pointing, is (in the Vega system) $K_s \approx 20$ mag, $H \approx 21$ mag, $J \approx 22$ mag. Some preliminary results are presented here to illustrate the capabilities of the ongoing survey. We expect to obtain accurate redshift values, $\Delta z/(1+z) \leq 0.03$ for about 5×10^5 galaxies with $I \leq 25$ (60% completeness level), and $z_{med} = 0.74$. This accuracy, together with the homogeneity of the selection function, will allow for the study of the redshift evolution of the large scale structure, the galaxy population and its evolution with redshift, the identification of clusters of galaxies, and many other studies, without the need for any further follow-up. It will also provide targets for detailed studies with 10m-class telescopes. Given its area, spectral coverage and its depth, apart from those main goals, the ALHAMBRA-Survey will also produce valuable data for galactic studies.

Subject headings: photometric surveys – photometric redshifts – cosmic evolution – cosmology

1. Introduction: Global scientific aim and opportunity

Only over the last few years it has become possible for Observational Cosmology to gather enough data on the distant universe to feed our comprehension of the evolution of the different objects that populate it. It has become almost commonplace to study protogalaxies at redshifts $z > 5$, and to observe particular objects at redshifts as high as $z \approx 6.5$ (Becker et al. 2001, Kashikawa et al. 2006, Kawai et al. 2006) or even $z \approx 7.5$ (Bradley et al. 2008). At the same time, samples of objects have been collected through different techniques at smaller

¹Based on observations collected at the German-Spanish Astronomical Center, Calar Alto, jointly operated by the Max-Planck-Institut für Astronomie Heidelberg and the Instituto de Astrofísica de Andalucía (CSIC).

distances (and shorter evolutionary times) from us, and the different properties of objects in separate redshift ranges have been measured and compared. However, it remains true that to this day, no homogeneous sample of objects has been collected covering a significant range of the age of the universe, even if some remarkable efforts have been devoted to the production of wide-field, shallow surveys, that cover the low-redshift end (like 2dFGRS, Colless et al. 2001, SDSS, York et al. 2000, VVDS, Le Fèvre et al. 2005 or DEEP-2, Davis et al. 2003) while other groups have directed their efforts towards the most distant end, through very deep, small-area surveys like the HST Deep Fields or other legacy programs (Ferguson et al. 2000, Beckwith et al. 2006).

The Cosmological Principle implies the existence of maximally symmetric subspaces and the existence of a one-to-one relation between redshift and time. The corresponding evolutionary nature of the depicted Universe is a model-independent prediction, prior to any consideration about the value of the cosmological parameters. A direct way to tackle many of the problems posed by modern cosmology is hence to materialize a *foliation of the space-time*, producing narrow slices in the z -direction whereas the spatial sections are large enough to be cosmologically representative, obtaining as output a kind of *Cosmic Tomography*.

From the observational point of view, to trace *Cosmic Evolution*, which is a central topic in Cosmology, the genuine evolutionary effects have to be disentangled from both the physical variance at a given redshift and the details of the metric as measured in — or, depending on the point of view, induced by — the cosmological model. In other words, to approach the question of evolution meaningfully it is necessary to sample large volumes even at low redshift, to capture not only representative average properties but also their variance. This will necessarily imply a survey featuring a combination of wide area and depth, and a continuous spectral coverage to avoid complex selection functions that depend on the redshift and on the nature of the objects under analysis. Moreover, the quest for the necessary precision implies high enough spectral resolution and photometric accuracy.

Up to now, the largest surveys ensuring complete spectral coverage for large samples have been photometric, and done with broad-band filters. The resulting redshift precision obtained with these techniques (~ 0.03 in $\Delta z/(1+z)$, at best, see Cucciati et al. 2006 and Ilbert et al. 2006) and in Spectral Energy Distribution (SED) determination are correspondingly rough. Moreover, large area photometric surveys like SDSS are necessarily shallow, whereas deeper surveys have sampled the distant and/or faint Universe in rather small areas. At the other extreme in spectral resolution, spectroscopic surveys can neither go as deep as the photometric ones nor cover large enough areas. Moreover, they are defined in order to observe a restricted spectral region, producing a selection effect that is a function of the object type and redshift that can be very intricate due to the selection effects inherent

to spectroscopy (Fernández-Soto et al. 2001).

For those scientific purposes where the detailed properties of individual objects are not the goal, the aim from an observational stand is therefore that of finding the optimal filter combination to produce the most homogeneous, deepest, and most accurate possible photometric survey. Such a survey would produce precise enough values for the redshift and SED for large numbers of objects. We present here the **A**dvanced **L**arge **H**omogeneous **A**rea **M**edium **B**and **R**edshift **A**stronomical, **ALHAMBRA**-Survey, that intends to produce such an optimum survey for the study of cosmic evolution. It has been designed to achieve (with the facilities at hand) the best compromise between large area and depth, good spectral resolution and coverage, in order to produce an optimum output in terms of redshift and SED accuracy. The ALHAMBRA-Survey is a deep photometric survey using 20 contiguous, equal-width, medium-band optical filters from 3500 Å to 9700 Å, plus the three standard broad band (JHK_s) NIR filters. The total area surveyed by ALHAMBRA will be 4 square degrees, being therefore placed halfway in between traditional imaging and spectroscopic surveys.

By design, the ALHAMBRA-Survey will provide precise ($\Delta z < 0.03(1+z)$) photometric redshifts and SED classification for several hundred thousand galaxies and AGNs, allowing for different kinds of analysis regarding populations and structures, and their evolution in time. The details of the project, including simulations and expected results, and all the related aspects are described in the ALHAMBRA-Book that can be found at <http://www.iaa.es/alhambra>. Thanks to the unbiased nature of this survey (i.e. neither designed to detect a given class of objects nor to be precise only in some fixed spectral window), important problems other than cosmic evolution can be addressed. These include the study of stellar populations in the galactic halo, the search for peculiar stellar objects, ranging from very cold stars to blue stragglers, and the possible detection of debris from galactic satellites in the Milky Way halo. Moreover, the large surveyed volume and the ability to finely discriminate between different spectral energy distributions will permit the serendipitous detection of objects that could be classified as *exotic* or *rare*. This broad category includes very high redshift galaxies (≈ 2500 objects at $z > 5$, with $\Delta z < 0.01$, expected from scaled HDF observations) and QSOs.

The observations are being carried out with the 3.5m telescope of the Centro Astronómico Hispano-Alemán, CAHA, Calar Alto Observatory (Almería, Spain) and the wide-field imagers in the optical (LAICA) and in the NIR (Omega-2000). The collected data render possible the study of many different astronomical problems in a self-contained way and will provide with very interesting targets for individual studies with large size telescopes.

A separate article (Benítez et al. 2008) deals with the selection of the optical filters and

the optimization of their characteristics to maximize the spectral information, while in this work we present the main characteristics that specifically define the ALHAMBRA-Survey, including some preliminary results from the data we have already accumulated.

This paper is organized as follows: in Section 2 we present the project implementation and its present status, and in Section 3 the first, preliminary results. We compare the ALHAMBRA survey with other surveys in Section 4, whereas our conclusions are presented in Section 5.

2. Survey design, implementation and status

2.1. Description of the filter system

The idea to use photometric information to determine the redshift of faint sources was first proposed by Baum (1962), and later re-launched by Loh & Spillar (1986), Koo (1986) and Connolly et al. (1995) as a *poor person* redshift machine. Its importance and adequacy to produce relevant data to different cosmological analysis was recognized after, among others, the works by Lanzetta et al. (1996), Connolly et al. (1997), or Fernández-Soto et al. (1999), on the Hubble Deep Field. Nowadays, many if not most of the surveys which have already been completed or are under development, include the use of broad-band filters and photometric redshift techniques.

Hickson et al. (1994) were the first to discuss the possibility of using a set of medium-band filters to continuously cover a large spectral range, and produce photometric data that could be considered equivalent to a very-low resolution spectrum for each detected object. No discussion was done however in that work on the number and kind of filters that would be needed in order to optimize the output in terms of z and SED accuracy for a given instrumental setup and observing time. Later the surveys CADIS (Meisenheimer et al. 1998) and COMBO-17 (Wolf et al. 2001a, Wolf et al. 2001b, Wolf et al. 2004, Bell et al. 2004) used a combination of broad- and medium-band filters with similar purposes. In particular, COMBO-17 employs the standard broad band filters ($UBVRI$) plus 12 narrow- or medium-band filters sampling several spectral domains between 4000 and 9200 Å. At the end, in this and similar surveys the full spectral coverage is obtained via broad band filters. COMBO-17 has reached very good quality in getting photometric redshifts with an accuracy of 1% in $\Delta z/(1+z)$ at $R < 21$. It covers an area of 1 square degree. The degradation in quality at fainter magnitudes is planned to be compensated with the use of 4 redder filters (Y , $J1$, $J2$ and H) in the MANOS-deep survey (or COMBO-17+4) covering a field of 0.77 square degrees.

The ALHAMBRA-Survey was designed to cover all the visible spectral domain with equally wide, contiguous medium-band filters to optimize its scientific output in terms of accuracy of the z and SED determinations. By design, it is possible to detect, other than the overall SED, relatively faint emission lines. As already pointed out, the details are explained in a separated paper by Benítez et al. (2008), where different implementations were devised and analyzed to get the best solution for a given fixed total amount of observing time. The resulting optical filter system includes a total of 20 contiguous, medium-band, $\text{FWHM} = 310 \text{ \AA}$, top-hat filters, that cover the complete optical range from 3500 to $9700 \text{ \AA}$. The optical coverage is supplemented with the standard NIR JHK_s filters.

The filter set was designed having in mind a series of restrictive requirements about their spectral shape, homogeneity, and transmission. In particular, all filters should have very steep side slopes, close to zero overlap in λ , a flat top, and transmissions in excess of 70%. Given the particular disposition of the four detectors in the LAICA focal plane, four sets of filters had to be produced, in such a way that all of them were equivalent within strict limits. The complete set of 20×4 filters was manufactured by BARR Associates. They were confirmed to be within specifications at the laboratory of the Instituto de Astrofísica de Andalucía. The transmission curves are shown in Figure 1.

2.2. Expected redshift precision and the NIR filters

For a survey with the characteristics of ALHAMBRA the quality of the final results depends critically on the photometric errors and the adequacy of the templates used to compute photometric redshifts. To test the first aspect we have created a grid of galaxy spectra using the templates presented in Benítez (2000), with redshifts between 0 and 5.0, and absolute K_s -band magnitudes ranging from -23 to -16. All these galaxies have been "observed" through the full ALHAMBRA photometric system, with noise added to the observed fluxes according to the properties of our data. Each galaxy had then its ALHAMBRA photometric redshift measured via the same code used by Fernández-Soto et al. (1999), and the offset between the original and the calculated values of the redshift was obtained. We have then binned the objects according to their photometric I -band magnitude uncertainty, and estimated the dispersion around the correct redshift value for each bin. The results are presented in Figure 2, where it can be seen that we obtain an excellent redshift accuracy ($\Delta z/(1+z) < 0.03$) even for objects with magnitude errors as large as $\Delta AB(I) \approx 0.15$ —the error we measure for typical objects at $AB(I) \approx 24.5$. Moreover, the percentage of all those objects that actually have redshift residuals smaller than that is larger than 50%—recall that the redshift error distribution is strongly non-Gaussian, with long tails and second peaks due

Fig. 1.— Transmission curves for one of the optical filter sets for the ALHAMBRA-Survey as measured in the laboratory. We also show the effective total transmission (lower curve), after taking into account the quantum efficiency of the CCD detector, the atmosphere transmission (at Air Mass = 1.3) and the reflectivity of the primary mirror of the Calar Alto 3.5m telescope

to the so-called "catastrophic errors". This analysis, of course, does not include the possible systematic effects induced by the choice of the template set.

Inclusion of the NIR information can significantly improve the determination of the redshift in some cases. In particular, as pointed out by many authors using photometric redshift techniques in deep surveys (*e.g.* Coe et al. 2006), the use of NIR filters can help to break the degeneracy between low-redshift ($z \approx 0.5$) and high-redshift ($z \approx 3$) galaxies. The reason behind this degeneracy is the possible confusion between the Balmer and Lyman breaks, which are the most salient features of the respective spectral energy distributions. In absence of any infrared information, it is not possible to determine the slope of the rest-frame red end of the spectrum, the range that can in fact tell the difference between both families. Each one of the left-side panels in Figure 3 explicitly shows the degeneracies between the different spectral types and redshifts. For each of the six galaxy types used in the exercise (rows and cells) and every redshift (from $z = 0$ to $z = 8$ in both axes in every box), the points mark the types that degenerate with it in color space—for this particular figure, a magnitude "thickness" $\Delta m = 0.2$ has been chosen, so that any two galaxy spectra that differ in less than Δm in all the ALHAMBRA filters considered have been taken as degenerate, and hence indistinguishable.

It can be seen in the right-side panels how (for the $\Delta m = 0.2$ case) the presence of NIR data eliminates most of the degeneracies between low and high redshift, and sharply separates the elliptical, Sab, and Scd galaxies from the rest and from each other, leaving only some residual degeneracy between the three bluest types. Of course, the infrared information also adds greatly to the scientific content of the survey, via the more direct relation existing between the galactic mass and the infrared luminosity.

Our preliminary results (see next section) show us that the simulations above should not be far off the mark; our I -band photometric errors are $< 10\%$ up to $I \approx 24$, with expected redshift errors $\delta z / (1 + z) \leq 1.5\%$. We also expect that most of the objects up to $I \leq 25$ will have photometric redshift errors $< 3\%$.

2.3. The Survey area

It is well known that astronomical objects cluster on the sky on different scales. The clustering signature contains a wealth of information about the structure formation process. A survey designed to cope with the cosmic variance and to describe and understand the clustering needs to probe as many scales as possible, up to the homogeneity scale. So, on one hand, searching contiguous areas is important in order to cover smoothly the smallest scales

Fig. 2.— Estimates of the photometric redshift dispersion as a function of the photometric uncertainty in the I band. The black dots and continuous line show the velocity uncertainty, while the red dotted (green dashed) line shows the percentage of objects with a given I -band uncertainty that have redshift residuals smaller than $\Delta z/(1+z) = 0.015$ (0.030).

Fig. 3.— Theoretical degeneracies in type and redshift expected for galaxies in the ALHAMBRA survey measured to an accuracy of 0.2 magnitudes in all filters. The upper panel shows the case where no infrared information is available, and the lower panel corresponds to the case where the NIR information is included. Each of the 6×6 sub-panels corresponds to a z_1 (photometric redshifts) vs z_2 (actual values) diagram with redshifts ranging from 0 to 8.

Table 1: The ALHAMBRA-Survey Fields. We include together with the name a reference to overlaps with other surveys of interest.

Field name	RA(J2000)	DEC(J2000)	100 μm	E(B-V)	l	b
ALHAMBRA-1	00 29 46.0	+05 25 28	0.83	0.017	113	-57
ALHAMBRA-2/DEEP2	02 28 32.0	+00 47 00	1.48	0.031	166	-53
ALHAMBRA-3/SDSS	09 16 20.0	+46 02 20	0.67	0.015	174	+44
ALHAMBRA-4/COSMOS	10 00 28.6	+02 12 21	0.91	0.018	236	+42
ALHAMBRA-5/HDF-N	12 35 00.0	+61 57 00	0.63	0.011	125	+55
ALHAMBRA-6/GROTH	14 16 38.0	+52 25 05	0.49	0.007	95	+60
ALHAMBRA-7/ELAIS-N1	16 12 10.0	+54 30 00	0.45	0.005	84	+45
ALHAMBRA-8/SDSS	23 45 50.0	+15 34 50	1.18	0.027	99	-44

where the signal is stronger and to obtain an optimally-shaped window function. But, on the other hand, measuring a population of a certain volume density is a Poissonian process with an associated variance and, in principle, one would obtain different densities of the same population when measuring at different places. The variance in those measurements is dictated by the volume density of the population under study, the volume searched and the clustering of the population. In order to beat down this cosmic (or, technically, sampling) variance one needs to survey independent volumes. So, all in all, a balance must exist between probing contiguous and independent areas.

For a survey aiming at resolving a number N_{st} of SED-types, the sampling errors in any counting statistical measure will go as

$$\sigma_s = K \sqrt{\frac{N_{st}}{N_f \Delta z}}$$

where N_f is the number of fields of a given area and Δz the redshift interval to be resolved. To get a quantitative evaluation of this statistical noise, we have used the SDSS local luminosity function, that yields, with a plausible parameterization of the evolution, a redshift distribution similar to that obtained from the HDF at our magnitude limit. Expressing N_f as the number of 1 square degree fields, we find K in the range 0.01 - 0.02 for redshift between 0.3 and 2. Therefore, if we intend to have relative sampling errors no larger than a few percent at any redshift, with a redshift resolution better than $\Delta z = 0.05$, N_f should be similar to N_{st} , which results in a total field of a few square degrees.

On the technical side we had to consider the geometry of the imager LAICA, with four 4k×4k CCDs, arranged in a 2×2 mosaic with the gap between two adjacent (vertical

and horizontal) CCDs being almost the same size of the CCD itself. Thus, one pointing corresponds to 4 patches of $15.4' \times 15.4'$ over a total field of $44.4' \times 44.4'$, such that with four pointings a total, contiguous area of 1 degree squared is covered². This geometry imposes a minimum contiguous area patch of 1 degree $\times$ 0.25 degrees and produces 2 such strips in two pointings. The Omega-2000 camera used for NIR observations³ covers a field of view equivalent to one of the LAICA CCDs.

Considering the sampling constrains together with the technical characteristics of the detectors, the expected efficiency of the atmosphere-telescope-imager, and the amount of available time for the project, we finally decided to cover 2 such strips in each of the 8 selected fields, a total of 4 square degrees to ensure a large enough area coverage and good sampling.

The fields were selected taking as first and basic criterion their low extinction, as measured in Schlegel et al. (1998). Then, within the lowest extinction patches, we tried to identify those containing neither bright sources nor conspicuous structures. We decided that a significant overlap with other surveys would be an asset, to ensure the possible cross-checking of our results and maximum complementarity, in particular regarding the largest coverage in wavelength. The selected fields are listed in Table 1. The $100\ \mu\text{m}$ emission and $E(B-V)$ values quoted in the table are the median for the whole 1° field centered at the given position. Only ALHAMBRA-1 is new in the sense of having no overlap with other surveys.

At the moment of writing this article (Feb 2008) we have already obtained about 64% of the near infrared data and about 35% of the visible data. The NIR observations with Omega-2000 were started in August 2004, whereas we could start taking visible data with LAICA only in September 2005. We expect to complete our observations by 2010.

We will discuss in Section 3 below some preliminary results obtained with our first complete $15' \times 15'$ pointing, including observations with all the ALHAMBRA filters.

2.4. The calibration strategy

As mentioned above, we have already completed the first LAICA pointing in all the filters. In the quoted ALHAMBRA-book we have presented the simulations we performed to design the survey and to find the expected depth of the data for the strategy chosen.

²<http://www.caha.es/CAHA/Instruments/LAICA/index.html>

³<http://www.mpia-hd.mpg.de/IRCAM/O2000/index.html>

We are now in the position of checking the quality of the data delivered by the survey, the validity of our simulations and the adequateness of our observational strategy

Indeed, a crucial aspect to do that analysis is the photometric calibration of the data. This is a particularly demanding aspect of the project. Apart from other considerations, it has been shown that the reliability of the photometric redshifts depends critically on the photometric accuracy (Coe et al. 2006). This aspect is particularly acute in our case since we are in fact introducing a new photometric system in the optical domain. Thus, special care is needed to anchor it to existing photometric systems and to primary calibrators.

To define the reference fluxes and magnitudes of the ALHAMBRA photometric system we have chosen a set of primary stars from the lists by Oke & Gunn (1983), Oke (1990), Massey & Gronwall (1990) and Stone (1996), together with the 4 fundamental calibrators adopted by the HST. The list includes the standard star BD+17°4708, the primary calibrator of the SDSS system.

We give here a short account of calibration procedure, whereas the details will be presented in a forthcoming article. The devised procedure starts with the selection of stars in our frames that have SDSS photometry. These will play the role of secondary standards. We plan to obtain spectrophotometric observations of all these stars, calibrated with respect to those primary standards. The spectra will then be fitted by stellar models and the ALHAMBRA-system colors will be obtained from the fitted models by integration over the filters. We will also compare the synthetic $u'g'r'i'z'$ colors with the SDSS values to check the consistency between the systems. In this way we expect to have a calibration accurate to the 2% level or better. The comparison between photometric and spectroscopic redshifts for the galaxies with spectroscopic observations will also be used as a check of the calibration of the ALHAMBRA data (Coe et al. 2006).

We will set the ALHAMBRA magnitudes on the AB system (Oke & Gunn 1983),

$$AB_\nu = -2.5 \log f_\nu - 48.60$$

where f_ν is the flux per unit frequency from an object in $\text{erg s}^{-1} \text{cm}^{-2} \text{Hz}^{-1}$.

The magnitudes will be defined with reference to their spectrophotometric data by adopting

$$m = -2.5 \log \frac{\int_F f(\nu) S_F(\nu) d(\log \nu)}{\int_F S_F(\nu) d(\log \nu)} + \text{Cte}$$

where $S_F(\nu)$ is the transmission curve corresponding to the atmosphere-telescope-filter-detector combination.

This is in fact the usual way to calibrate narrow-band images when the photometric

system is not previously defined (see for example, Márquez & Moles 1996). The SDSS Consortium has also adopted this strategy to define their own photometric system (Fukugita et al. 1996; Smith et al. 2002).

At the moment of writing the present paper we have not yet completed the observations of secondary stars to get the final calibration. In order to get a preliminary calibration that would be robust and accurate enough to allow the analysis of the main aspects of the survey in terms of depth and reliability, we have implemented a different procedure. Briefly, what we have done is to select 228 flux calibrated stellar spectra from the Hubble’s Next Generation Spectral Library (NGSL; Gregg et al. 2004) covering a wide range of physical properties. From these spectra synthetic colors were obtained in both, SDSS and ALHAMBRA systems and the first set of transformation equations between the two systems were obtained. The results are given in Table 2.

Then we have applied these equations to a set of stars with accurate SDSS and ALHAMBRA instrumental magnitudes to obtain the zero point of the photometric calibration. The zero points found in this way are accurate at the level between 5 and 10%.

The NIR data have been calibrated through the 2MASS catalog stars present in our frames. The rms of the calibration is always below 0.04 mag in all 3 bands.

2.5. Observing Strategy

As was mentioned in Section 2.1, the ALHAMBRA filter set was devised following detailed simulations in order to optimise the quality and number of photometric redshifts for galaxies in our fields. Similarly, the exposure times per filter were defined in such a way that the expected magnitude limits in each one would be as homogeneous as practically possible. This driving principle, combined with a minimum exposure time of 2.5 ksec per filter (due to the observing logistics), and the known fact that our system is less efficient in the red end of the spectrum, propped us to divide the total LAICA time per pointing (100 ksec) in the way presented in Figure 4. Thus, the target $AB = 25$ limit would be reached or even exceeded for all filters bluewards of $\approx 8500 \text{ \AA}$, and redwards from there the decreasing efficiency makes the limit magnitude drop until $AB \approx 23$ at $\approx 9500 \text{ \AA}$. In the near infrared, previous experience with Omega-2000 decided us to divide the available 15ksec per pointing equally into the J, H, K_s filters, aiming to reach $J = 22, H = 21, K_s = 20$ (in the Vega-based system). These expectations will be compared with the real data in Section 3.

Our image quality limit to consider the data as ”scientifically valid” is, in real time at the telescope dome, a value of the seeing which should be $< 1.4''$. However, the seeing,

Fig. 4.— Expected limit magnitudes for the ALHAMBRA filters, at S/N = 5, estimated for our survey. The exposure time per filter (in ksec) is given for every filter.

as well as the transparency, is measured *a posteriori* during the pipeline reduction, and the individual images are kept or eliminated from the final combination based on a more complex quality assessment, that will be presented elsewhere.

2.6. Data reduction

For the reduction of the images two different pipelines have been used. In the case of the LAICA data, the preliminary standard steps of overscan correction and flat-fielding are performed. After that, the illumination correction using smooth superflats is applied. In the optical filters redder than 7000 Å the images suffer from a substantial fringing pattern that is removed using the procedure described in Alcalá et al. (2002). This fringing pattern contributes less than 2% to the flat-fields, so we have not corrected the flat-fields at this stage.

In the case of the NIR filters we first removed the dark current frames and divided by a normalized superflat constructed combining the science images. An additive pupil ghost is present in the superflat images, that is more prominent in the *J* band ($\sim 5\%$ contribution). The pupil ghost is fitted in the normalized flat-field images using the `mscpupil` task in the IRAF MSCRED package (Valdes 2002). The adjusted pupil pattern (p_{ij}) is removed from the flat-field dividing it by $(1+p_{ij})$, and is subtracted from the individual images after scaling it by the median background level. After having flat-fielded the images, the sky structure of each individual image is removed with the XDIMSUM package (Stanford, Eisenhardt & Dickinson 1995) using the sky image constructed with the median of the 6 closest images, that in case of the *J*, *H*, *K_s* filters correspond to timescales of 480,360,276 seconds respectively. Before removing the background, the sky image is median filtered using 5×5 window in order to reduce its noise. During this process also masks for each individual image with the location of the cosmic rays are created. The cosmic rays and bad pixels are fixed to proceed with the next steps.

At this stage, the sky level is measured, and SExtractor (Bertin & Arnouts 1996) is used to obtain an initial estimate of the FWHM of each image, and the number of sources above a given S/N. The relative transparency of each image is measured using high S/N stars. These numbers are used to remove bad images or images out of the survey requirements. After that, the astrometry of a reference image is calibrated using the USNO-B1.0 (Monet et al. 2003) catalog. The external astrometric rms is ~ 0.12 arcsecs in each axis. The remaining images are calibrated internally, in a first iteration using the reference image in the filter. After completing an ALHAMBRA pointing a deep image constructed using images with good FWHM and transparency in several selected filters will be created and used afterwards to

calibrate the internal astrometric solution. For this purpose we have used our own algorithm to match the image sources with those in the external catalog, and the IRAF ccmmap task to obtain an order 3 polynomial solution. The internal astrometric solution rms is ~ 0.03 arcsec in each axis for the Laica images and ~ 0.05 arcsecs in the Omega-2000 ones. Finally, the astrometry of each individual image is re-calibrated internally with the reference image using Scamp⁴ obtaining similar results. For image combination Swarp⁵ is used. This software takes into account the distortion pattern present in the wcs headers, and allows the user to obtain resampled images with a different pixel size, in the desired sky projection. Also the previously computed relative transparency is used to uniform the zero points of the individual images. In our process, before performing the final combination using Swarp, the resampled images are used to apply a pixel rejection algorithm in order to improve the cosmic ray rejection and bad pixel masks. In the case of the Omega-2000 images, with a roughly double pixel size, we also require a final image with the Laica pixel scale. The final images for each ALHAMBRA pointing in the 23 filters are registered within the internal astrometric solution rms.

3. Survey performance: preliminary results

The ALHAMBRA survey and filter system design was preceded by realistic, thorough simulations presented in Benítez et al. 2008 and in the ALHAMBRA-book. Recently we completed the observations of the first pointing in the 20+3 filters, comprising 4 times a $15'4 \times 15'4$ field, and we are thus able to compare the performance of the survey with our expectations.

We show in Figure 5 a color image corresponding to one of the CCDs of the first complete pointing in the ALHAMBRA-8 field (see Table 1). An enlargement of this image of approximately 1.5 arc-minutes side, where a small group of spiral galaxies can be seen, is shown as an insert in the same figure.

These data allow us to go from simulations to actual measurements, and describe several key characteristics of the survey; others will have to be complemented with simulations until we carry out follow-up observations, primarily due to the paucity of available spectroscopic redshifts in this particular field.

⁴<http://terapix.iap.fr>

⁵<http://terapix.iap.fr>

Fig. 5.— The first complete pointing of the ALHAMBRA-8 field in a square region of 15 arc-minutes side. This color image has been created making use of data from 14 out of the 23 filters. In the insert, corresponding to a region of about 1.5 arc-minutes, a small group of galaxies can be seen

3.1. Photometric depth

The data reduction procedure involves the standard steps, including accurate flatfielding and defringing (for the red filters) and precise astrometry. SExtractor, with just standard settings for the different parameters, was used to get the photometry of the detected objects that we discuss here. The pipelines and procedures will be described in a separate paper, and will be made publicly available. Then the data were photometrically calibrated following the procedure sketched in the previous section.

The ALHAMBRA filter system was primarily designed to obtain the best determination of z and SED for a fixed amount of observing time per pointing (100 ksec). We estimated the expected limit magnitudes taking into account the average extinction in Calar Alto, the performance of the 3.5m telescope-LAICA system for airmass = 1.3, a final image quality of FWHM $\approx 1''.2$ and the measured filter+CCDs transmission curves. The goal was to get homogeneous magnitude limits for as many filters as possible, with the restriction that the minimum exposure time per filter should not be less than 2.5 ksec. We expected to reach AB ≤ 25 (S/N = 5, point-like source) for 16 filters ranging from 3500 Å to 8500 Å. In the case of the four reddest filters (close in wavelength to the z band) we could obtain decreasingly lower limit magnitudes, down to AB = 23.4 in the last filter centered at 9550 Å (see the quoted ALHAMBRA-book and Moles et al. 2005).

To ascertain in a quantitative way the actual depth we reach in each of the filters we have defined the limiting magnitude as that corresponding to the rms within a 1 square arc-second aperture, at the S/N = 5 level. The values we find are plotted in Figure 6. As can be seen, we are actually reaching the expected limits in all the filters, including the reddest ones. We also show in the same figure the magnitude limit values for a $2 \times \text{FWHM}$ aperture, which may represent a more realistic integration area for typical flux measurements.

A complementary way to illustrate the depth of the data is to consider the number counts in each band. In Figure 7 we show the preliminary number count histograms in the 20 ALHAMBRA optical filters. The counts have been normalized to unit magnitude and unit area (square degree). No corrections due to completeness or spurious detection have been applied. The histograms indicate that we are detecting sources at AB ≤ 25 in all the filters from the bluest to about 8000Å. The limiting magnitude then becomes brighter, and we end up with AB $\sim$ 23 at 9500Å.

Moreover, to be able to compare with broad-band and spectroscopic surveys (see later), we have synthesized broad-band filters from our medium-band ALHAMBRA filters. In Figure 8 we present the results for the I^* (synthetic I) band. It can be seen that the survey is complete to $I^* \approx 25$ with errors $\approx 20\%$ in the worst cases.

Fig. 6.— The limit magnitude, at $S/N = 5$ in each filter, for $1''$ square aperture and for an aperture of $2 \times \text{FWHM}$ diameter. The total observing time per pointing was fixed to 100 ksec for the 20 optical filters, and to 15 ksec for the NIR bands

Fig. 7.— Histograms of number of sources to $S/N=5$ per square degree per magnitude for the 20 ALHAMBRA optical filters.

Fig. 8.— Counts as a function of isophotal magnitude in the synthetic I-band image. The completeness limit is close to $I(AB) = 25$. In the inserted panel the photometric errors as a function of the isophotal I magnitude are shown.

In the NIR, based on existing experience with Omega-2000, we fixed the total exposure time to 5 ksec per filter, in order to reach $K_s \approx 20$, $H \approx 21$, $J \approx 22$ in the Vega system ($S/N = 5$, point like source). The limit magnitudes presented in Figure 6 and the histograms presented in Figure 9 show that these limits have been reached, and even exceeded⁶. A more detailed analysis of the NIR galaxy counts will be presented in Cristóbal-Hornillos et al. (2008, *in preparation*).

3.2. Photometric redshift depth and accuracy

The central goal of the ALHAMBRA-survey is to measure with precision the observed photometry of as many objects as possible; this enables us to estimate accurate redshifts and spectral types. The use of a large number of filters, contiguous and with minimal overlap among themselves provides a clear, unequivocal representation of the galaxy SED. This is well illustrated by Figure 10 which shows a small (0.7×0.7 arc-minutes) thumbnail image of a $AB(I) \approx 23$ object in the ALHAMBRA-8 field in all 23 ALHAMBRA images and the synthetic $U^*B^*V^*R^*I^*$ filters, together with a calibrated ALHAMBRA “spectrum” of the object, a starburst with $z = 4.23$.

The customary way of determining the photo- z accuracy of a survey is comparing estimates with a large sample of spectroscopic redshifts; unfortunately, the first field which we have completed only has SDSS spectroscopy available, too shallow and sparse for that purpose, and we plan to carry out spectroscopic follow-up observations for this and other fields.

The NASA Extragalactic Database contains nine galaxies with spectroscopic redshifts within the limits of our $15' \times 15'$ pointing, all of them SDSS galaxies (Adelman-McCarthy et al. 2007), with redshifts in the range $z \lesssim 0.2$. Despite the inadequacy of this sample for statistical purposes it allows us to give the reader a taste of the redshift accuracy of the ALHAMBRA survey (see Figures 11 and 12).

We are presently using three different codes to measure photometric redshifts, based on different methods, in order to eventually choose the most robust and accurate strategy.

a) One is the code developed by Fernández-Soto et al. (1999), based on galaxy template fitting with an extended Coleman, Wu and Weedman (1980) library comprising six templates.

⁶Recall that the magnitude difference (AB-Vega) for the J , H , and K_s filters is ≈ 0.9 , 1.5 , and 2.0 respectively.

Fig. 9.— Histograms of number of sources to S/N=5 per square degree per magnitude in the three NIR filters.

Fig. 10.— Upper panels: Images through all 23 ALHAMBRA filters and the synthetic Johnson filters for a single object in the ALHAMBRA-8 field, marked with horizontal ticks. Each 0.7 arcmin square thumbnail is labeled with its wavelength in nanometers, or the filter name. Lower panel: ALHAMBRA-spectrum of the same object. The vertical dashed lines mark the putative positions of Lyman- α , Lyman- β , and the Lyman limit, at the measured redshift $z = 4.32$. Note that the 427nm image and data point are noisier because we did not use the complete exposure time for this filter in this preliminary reduction.

b) The second one is the BPZ program, as described in Benítez (2000), which uses a Bayesian magnitude-type prior and the empirically calibrated template library described in Benítez et al. (2004) and complemented with two very blue starburst types (Coe et al. 2006), eight galaxy templates in total.

c) The third method has been recently implemented by Sánchez (2008, *in preparation*), and uses a synthetic library which also includes stellar spectra, AGN types and dust reddening. The use of a synthetic library provides information about the metallicity, the star formation history, and other characteristics of the object.

The empirically calibrated library of Benítez et al. (2004) has been shown to be precise enough to detect and calibrate photometric zero points errors within 2 – 3% as the ones in the NIC3 observations of the Hubble Ultra Deep Field (see Coe et al. 2006). Using this calibration technique to correct the COMBO-17 photometry presented in Hildebrant, Wolf and Benítez (2008) reduces the photometric redshift error from $\delta z/(1+z)$ from 0.038 ± 0.035 to 0.001 ± 0.023 . We therefore carry out a similar zero point recalibration using the 9 galaxies with spectroscopic redshifts. This recalibrated photometry is then fed to the three codes mentioned above. As expected, the agreement among them is good for bright objects, but somewhat breaks down at fainter magnitudes.

It is noteworthy that code c) predicts extremely well the redshifts of the spectroscopic sample: its photometric error is $\delta z \approx 0.000 \pm 0.010$ close to the theoretical accuracy (see Figure). The BPZ software yields $\delta z \approx 0.002 \pm 0.014$, but it mistakes the reddening of an edge-on spiral at $z = 0.09$ for a higher redshift, producing an outlier.

We will further test and refine our photometric redshift techniques, and the final strategy will probably include a combination of them, in order to make our measurements as robust as possible. As a token of the quality of the spectral information, we present the ALHAMBRA-spectrum of one of the SDSS galaxies in Figure 12 (SDSS coordinates 356.331030,+15.479499, redshift $z_{sp} = 0.113525$). Our best-fit redshift for this object is $z_{ph} = 0.12$. The magnitude offset between the SDSS spectrum and our photometry is present in the original data, and it must be due to the smaller flux falling within the SDSS spectrograph fiber. Our data, even with the preliminary calibration we are using at the moment, perfectly reproduce even some of the minor details in the spectrum.

In Figure 13 we present a mosaic of 3-color galaxy images sorted according to redshift (lines) and luminosity (columns). They span a large range in absolute magnitude (as measured in the band centered at 7370Å), from brighter than $M(AB) = -24$, to $M(AB) \approx -16.7$. The figure illustrates the depth of this preliminary catalogue and the redshift values that can be obtained.

Fig. 11.— Comparison of spectroscopic and photometric redshifts for the available sample. This plot makes use of the results obtained with the Sánchez (2008, *in preparation*) code described in the text. The statistics refer exclusively to the nine points represented in the plot.

Fig. 12.— ALHAMBRA-spectrum (points with error bars), best-fit model (smooth line); and SDSS photometry (diamonds) and spectrum (lower, noisy line) for one of the galaxies with spectroscopic redshift in the ALHAMBRA-8 field. The vertical ticks mark the expected position of the H α +NII complex at the best-fit redshift. Notice the apparent excess in the ALHAMBRA photometry at the expected wavelength, even though the total equivalent width measured for the complex in the SDSS spectrum is only 15 Å.

Fig. 13.— Postage stamp images of a set of galaxies extracted from the catalog of the field presented in this work. Each postage stamp has been generated using the $\lambda 3960\text{\AA}$ (blue), $\lambda 6750\text{\AA}$ (green) and Ks-band (red) frames to create a three-color image. The galaxies are ordered by increasing redshift in the X-axis and decreasing $\lambda 7370\text{\AA}$ absolute magnitude along the Y-axis, with each plotted galaxy being the most luminous of its corresponding redshift-luminosity box. The luminosity ranges from $M_{7370} < -24$ to $M_{7370} \approx -16.67$, and the redshift ranges from $z < 0.20$ to $z = 0.90$. Redshift and magnitude values for each column and line are given in the figure.

One of the defining characteristics of any photometric redshift survey is its effective depth, i.e. the magnitude limit at which it is still possible to measure precise photometric redshifts. If the photometric redshifts are estimated using a Bayesian formalism, it is possible to define a quantity called “odds” which serves as powerful quality indicator of the reliability and accuracy of a photometric redshift estimation (Benítez 2000, Benítez et al. 2004). The value of the odds represents the fraction of the probability $p(z)$ concentrated around the maximum z_{ph} . At fainter magnitudes the photometric noise degrades the redshift information and often $p(z)$ is multimodal or presents a single peak of large width, making unfeasible an unambiguous estimate of the redshift. Therefore by imposing cuts on the value of the odds we can select galaxy subsamples for which the redshift estimates are reliable and accurate; in fact it can be shown that the redshift accuracy depends on the severity of the threshold cut.

4. Comparison with other surveys

Several large, deep photometric and spectroscopic surveys, have been completed in the last years or are currently being conducted. Comparison between different surveys, each of them designed for specific purposes and with different strategies, is not straightforward. To put the ALHAMBRA-Survey in the context of other similar efforts we have plotted in Figure 16 their positions in an area-depth plane⁷. Only photometric surveys with 5 or more filters, i.e., those that can provide general redshift information, and area covered ≥ 0.5 square degree (with the exception of CADIS) were included. As we can see in this plot, the ALHAMBRA-Survey occupies a position in between the first generation of wide field photometric surveys—amongst which clearly COMBO-17 has played the leading role up to now—and the ongoing projects which try to map much larger areas with comparable depth like Pan-Starrs, DES, PAU, and LSST. COMBO-17 covers an area slightly larger than 1 square degree in five fields observed with the Wide-Field Imager at the MPG/ESO 2.2m telescope in La Silla (Chile). The large number of bands (five broad band filters *UBVRI* and 12 medium-band filters from 3500 Å to 9300 Å) has provided accurate measurements of photometric redshifts (Wolf et al. 2001a) to undertake ambitious scientific projects, being two of the last scientific achievements the measurement of galaxy clustering at moderate redshifts ($\langle z \rangle = 0.6$) (Phleps et al. 2006) and the analysis of 3D weak lensing (Kitching et al. 2007).

⁷Notice that the magnitude limits correspond in general to different spectral bands. In the particular case of IRAS/PSCz a typical *B* magnitude has been taken as indicative of the population, selected in the 60μ band.

Fig. 14.— The total number of galaxies we expect to detect in the ALHAMBRA-Survey (thick continuous), where we use the $F7374$ band as a proxy for the I band. The dashed and dotted line give the total number of galaxies with different odds thresholds (see text). These results are based on our first complete $15' \times 15'$ arc min² pointing. Our simulations predict the galaxies with odds > 0.99 and odds > 0.95 will have photometric redshift errors of $\delta \lesssim 0.015(1+z)$ and $\delta \lesssim 0.03(1+z)$ respectively.

Fig. 15.— The expected completeness level for the ALHAMBRA-Survey as a function of magnitude; here we use the $F7374$ band as a proxy for the I band. The dashed and dotted line correspond to different odds thresholds (see text). These results are based on our first complete $15' \times 15'$ arcmin² pointing. Our simulations predict the galaxies with odds > 0.99 and odds > 0.95 will have photometric redshift errors of $\delta \lesssim 0.015(1+z)$ and $\delta \lesssim 0.03(1+z)$ respectively.

As we have already indicated, the ALHAMBRA survey has been designed to provide a deeper photometric survey in the Northern hemisphere making use of 20 optical medium-band filters designed and optimised for the accurate determination of photometric redshifts (Benítez et al. 2008), covering four times the area covered by COMBO-17, and including from its design the standard NIR filters J, H and K. We are using in ALHAMBRA the 3.5 m telescope at Calar Alto, and therefore the gain in aperture and the use of infrared filters will make the ALHAMBRA survey deeper than COMBO-17. It is worth to say that also the COMBO-17 team has planned a NIR extension of its survey that will allow to reach $z \sim 2$ within its covered area (Meisenheimer et al., MPI technical report, 2005).

The ALHAMBRA-Survey compares favourably with other deep, large photometric surveys, even though it uses medium-band filters. It is only second in limit magnitude to a few broad band photometric surveys. Indeed, comparing the ALHAMBRA survey (not to mention spectroscopic surveys) with broad band ones in those terms is unfair, since the resulting accuracy in redshift and SED determination precision is significantly different. Thus, whereas typical redshift accuracies from those broad band surveys is ~ 0.1 in $\Delta z/(1+z)$ at best, we expect to reach 0.015 with ALHAMBRA for several hundred thousand galaxies.

A recent effort quantitatively similar to some degree to ALHAMBRA is the one presented by Mobasher et al. (2007), who have measured photometric redshifts in the COSMOS survey covering an area of $1.4^\circ \times 1.4^\circ$ containing 367000 galaxies down to $i \sim 25$ using 16 filters and providing accurate redshifts for faint galaxies up to $z \sim 1.2$. The reliability of their measurement has been tested comparing with the spectroscopy subsample zCOSMOS containing 868 normal galaxies with $z < 1.2$ (Lilly et al. 2007).

Spectroscopic surveys do of course achieve the highest redshift and SED precision but they cannot go as deep as photometric surveys, and not always have a complete spectral coverage, resulting in complex selection functions. Besides, the detection limit is not homogeneous along the spectrum, resulting in a lack of completeness which can prove very difficult to control. In some cases, for example when there is only one line in the spectrum, the photometric data can be used to reduce the ambiguity present in the spectroscopic measurements (Lilly et al. 2007). Given that our survey, in spite of its photometric nature, is closer in spirit to spectroscopic surveys, we discuss in the next paragraphs how it compares with them.

Indeed, the spectroscopic surveys can provide much more detailed information about individual objects than any medium-band photometric survey. However, for all those purposes where that detailed information is not needed, a survey like ALHAMBRA will prove advantageous due to the homogeneity of the detection in the different filters and the ability to produce accurate results even near the detection limit. Thus, as we wrote before, we

Fig. 16.— The position of different surveys in the area-depth plane. Only photometric surveys with a minimum of 5 filters and covering 0.5 square degree at least (with the exception of CADIS) are shown. Circles correspond to broad band photometric surveys, stars to spectroscopic surveys, and squares to CADIS, COMBO-17 and ALHAMBRA. Empty circles correspond to NIR imaging surveys.

expect to be 60% complete down to $I = 24.7$ mag with accurate z -determination, with a median redshift of 0.74. In Figure 17, we have plotted the expected global performance of different spectroscopic surveys in terms of surveyed volume and number of objects with good SED and redshift determinations. The ALHAMBRA-Survey appears close to the SDSS in terms of number of detected objects, and close to the deepest surveys in terms of its median redshift.

Another important advantage for the ALHAMBRA-survey is the spectral range covered. It is in fact the only survey covering the whole optical domain, from 3500 Å to 9700 Å, plus the 3 standard NIR bands. This implies that we are sensitive, within the detection limits, to any kind of object at any redshift. This not only avoids the presence of selection functions, but, more important, will straightforwardly allow the comparative analysis of data at different redshift values.

We have compiled in Table 2 the relevant data for the spectroscopic surveys plotted in Figure 17 (the number of objects in the ALHAMBRA survey is given for $\Delta z/(1+z) \leq 0.03$ and, in parenthesis, ≤ 0.015). For surveys with a similar (even if smaller) spectral coverage, like SDSS or 2dFGRS, the ALHAMBRA-Survey will be 7.8 and 6.7 magnitudes deeper, respectively, what will allow, in particular, for a detailed analysis of the distant/faint Universe. At the other extreme, surveys like VVDS or DEEP2 that are not too far from the ALHAMBRA-Survey in terms of limit magnitude (even if they are shallower by 1.2 and 2.7 magnitudes, respectively), have significantly shorter spectral coverage than ALHAMBRA in the optical domain, and do not include near-IR information.

Hickson & Mulrooney (1998) presented the first results of the medium band photometric survey proposed by Hickson et al. (1994). We notice that the survey used more filters than ALHAMBRA, thus giving a finer spectral sampling, but their spectral coverage is shorter, from 4450 to 9480 Å. The observing conditions were such that the survey could only reach $m \approx 20.4$, at the 50% completeness limit. Thus, even if similar in many aspects to our survey, a real comparison cannot be made given the bright detection limit they achieved.

In relation with other medium band photometric surveys, covering the whole spectral range, we have mentioned COMBO-17 and CADIS—which has also has made use of one of the Calar Alto telescopes—that comprise a mixed set of broad and narrow band filters. The complete spectral coverage is assured only by the broad band filters. Their specificity relies on the use of narrow filters located at some given fixed positions. The total area that they cover (1 and 0.2 square degrees respectively), the photometric depth, and the lack of near-IR information, are also important differences with the ALHAMBRA-Survey.

Yet another project making use of photometric redshifts and covering very large areas of

Fig. 17.— Number of detected objects with accurate redshift *versus* the surveyed volume for spectroscopic surveys covering 0.5 square degrees at least, and the ALHAMBRA-Survey. We have considered a median redshift of 0.02 for CfA2 and IRAS/PSCz, 0.08 for LCRS, 0.1 for SDSS/DR6 and 2dF, 0.7 for VVDS, 1.0 for DEEP2, and 0.63 and 0.74 for ALHAMBRA-90 (complete at the 90% level) and ALHAMBRA-60 (complete at the 60% level) respectively. The plotted ALHAMBRA data are for $\Delta z/(1+z) \leq 0.03$.

the sky, but with depth less than $z \sim 0.7$, is MegaZ-LRG (Collister et al. 2007), containing about a million SDSS luminous red galaxies, lying in a region of 5915 square degrees, with limiting magnitude $i < 20$. This catalog, with a surveyed volume of about $2.5 \text{ h}^{-3} \text{ Gpc}^3$, has been recently used to measure cosmological parameters from the large scale structure in a way competitive with the shallow wide-angle spectroscopic surveys (Blake et al. 2007). We must remark that an M_* galaxy lying at redshift $z \sim 1.4$ will be included in ALHAMBRA, since its visual magnitude should be about 24. At this redshift, the whole ALHAMBRA survey covering 4 square degrees will produce a volume of about $3 \times 10^7 \text{ h}^{-3} \text{ Mpc}^3$.

Other ongoing projects are the ESO/VST KIDS that will cover 1400 square degrees making use of images in 4 broad bands. Its major goal will be the study of weak lensing, although it should also be a good sample to study baryonic acoustic oscillations (Peacock et al. 2006), and the Dark Energy Survey, that makes use of a new camera on the CTIO 4m telescope. This survey will cover 5000 square degrees, but no near-IR observations are planned. Farther into the future, the LSST plans to map about half of the sky in the standard broad bands *ugrizy* to obtain about 3×10^9 photometric redshifts. The first light of this project is scheduled for 2012, and as Peacock et al. (2006) have pointed out, the lack of near-IR information may be an issue.

Different research projects devoted to the study of the evolution of galaxies across the Hubble time will get great advantage from the ALHAMBRA survey, when the complete catalog is released as publicly available. For example, this survey will increase the reliability of the present studies of the growth of the population of red galaxies since $z \sim 1$ (Ford et al. 2006) or the evolution with redshift of the color-density relation (Cucciati et al. 2006, Cooper et al. 2007). Other field where a deep and wide catalog like ALHAMBRA will be very useful is the analysis of the assembly history of red galaxies (Brown et al. 2008) or field spheroidals (Treu et al. 2005). Similarly, the ALHAMBRA survey covers enough area and is deep enough to trace accurately the evolution of the luminosity function for different spectral types (Poli et al. 2003, Treu et al. 2005, Wolf et al. 2003, Zucca et al. 2006, Marchesini et al. 2007) and the growth of stellar mass with cosmic time (Borch et al. 2006).

All in all, we can say that even if ALHAMBRA is a photometric survey, it shares important aspects with the spectroscopic surveys, with which it compares well in many respects. Its advantages, depending on the proposed goals, are the complete spectral coverage, the homogeneity in the detection level along the spectrum, and the depth.

5. Final Considerations

The ALHAMBRA-Survey places itself halfway between relatively shallow, limited spectral coverage, wide-area spectroscopic surveys, and deep, large area, broad band photometric surveys. Trying to optimally combine the advantages of each kind of survey, we intend to observe a large area (4°) using a specially designed set of 20 medium band, minimally overlapping filters covering the whole visible range from 3500 Å to 9700 Å, plus the standard JHK_s near infrared filters. It will provide homogeneous data down to $AB \approx 25$ for all the filters from 3500Å to 8500Å, with a magnitude limit of $AB = 23.2$ at 9550 Å. The filter characteristics were decided to allow us to detect even relatively faint emission features (observed $EW \geq 30\text{Å}$).

Together with the NIR information to $K_s \approx 20$, $H \approx 21$, $J \approx 22$ (in the Vega system), this will allow the measurement of the redshift and SED for several hundred thousand objects. Indeed, the survey was designed having in mind the use of photometric redshift techniques as the basic analysis tool. We have carried out detailed simulations based on available deep catalogs. We expect that the ALHAMBRA-Survey will be able to produce high-quality redshifts and accurate spectral types for more than 600,000 galaxies down to $I_{AB} \approx 24.7$, with redshift accuracy $\Delta z/(1+z) \approx 0.015$. The first data and preliminary results we present here confirm that these expectations are realistic.

With its volume surveyed, median redshift and number of objects with accurate redshift and SED determination, the ALHAMBRA-Survey will provide a unique set of data for many different studies in different astrophysical and cosmological domains.

The main objective of our survey is the study of cosmological evolution, under the many facets it can offer. We will study the evolution of the large scale structure, the number and content of clusters at different redshifts, the evolution of the populations of different cosmic

Table 3: Main characteristics of wide field (≥ 0.5 square degrees) spectroscopic surveys

Survey	Area $^\circ$	Spectral range (Å)	z (median)	$N_{objects}$
CfA/SRSS	18000	4300-6900	0.02	1.8×10^4
SDSS/DR6	6860	3800-9200	0.1	7.9×10^5
LCRS	700	3350-6750	0.1	2.6×10^4
2dFGRS	2000	3700-8000	0.11	2.2×10^5
VVDS	16	5500-9500	0.7	1.0×10^5
DEEP2	3.5	6500-9100	1.0	5.5×10^3
ALHAMBRA-60	4	3500-9700 (+ JHK)	0.74	$6.6 (3.0) \times 10^5$
ALHAMBRA-90	4	3500-9700 (+ JHK)	0.63	$3.5 (1.0) \times 10^5$

objects, and the processes leading to galaxy formation, evolution, and differentiation. The unbiased nature of the survey will also allow for the study of many different kinds of objects, ranging from emission-line galaxies to the diverse types of AGNs, and stars in our own Galaxy.

We acknowledge the decisive support given by the ALHAMBRA Extended Team to the project (see <http://www.iaa.es/alhambra> for the details regarding the project implementation and organization). We also wish to acknowledge the Calar Alto staff for their warm assistance for a fruitful start of the observations. We acknowledge the work of C. Cárdenas to measure the filter characteristics and of V. Peris for his work to produce the combined pictures out of the ALHAMBRA images. We thank our anonymous referee, whose comments helped to improve the clarity and quality of our manuscript. The authors acknowledge support from the Spanish Ministerio de Educación y Ciencia through grants AYA2002-12685-E, AYA2003-08729-C02-01, AYA2003-0128, AYA2004-08260-C03-01, AYA2004-20014-E, AYA2004-02703, AYA2004-05395, AYA2005-06816, AYA2005-07789, AYA2006-14056, and from the *Junta de Andalucía*, TIC114, TIC101 and *Proyecto de Excelencia* FQM-1392. NB, JALA, MC, and AFS acknowledge support from the MEC *Ramón y Cajal* Programme. NB acknowledges support from the EU IRG-017288. This work has made use of software designed at TERAPIX and the Canadian Astronomy Data Centre.
